INTRODUCTION

Despite urbanization being a relatively recent byproduct of the Anthropocene (Lewis & Maslin, 2015), already about 3% of Earth’s land surface is urban (Liu et al., 2014), with further increases projected throughout the remainder of the 21st century (Gao & O’Neill, 2020; Seto et al., 2012). Natural environments undergo marked transformations as a result of urbanization (Grimm et al., 2008), including modifications to landscape composition (e.g., loss of suitable patches, homogenization and connectivity; Groffman et al., 2014; McKinney, 2006), natural processes (e.g., soil pollution and nutrient cycling; Isaksson, 2015) and ecological interactions (e.g., competition, predation and pathogens; Rivkin et al., 2019). Subsequently, local biotic and abiotic interactions are altered and novel selection pressures thereby introduced, suggesting urban environments may be hotspots for microevolution (Alberti, 2015; Johnson & Munshi-South, 2017). Another hallmark of the Anthropocene appears to be biological invasions, as the worldwide dispersal of plants and animals is heavily influenced by international trade and humankind’s transportation network (Banks et al., 2015; Hulme, 2021). Like urbanization, these...
Invasions often promote ecological disturbance, whereby invasive species outcompete native species for resources or fill an empty ecological niche and alter the complexity of an ecosystem (Ehrenfeld, 2010). Similarly, ecological disturbance itself may encourage biological invasions by increasing the availability of resources (Lembrechts et al., 2016; Tilman, 1994) and/or altering the composition of communities (Buckling et al., 2000), potentially implicating urbanization as another human-induced facilitator of invasion. Ants are among the most prolific of these invaders (Jeschke & Wittenborn, 2011), with around 240 invasive species globally that display a significant association with disturbed environments (Bertelsmeier et al., 2017).

It is generally assumed that individual and colony-level plasticity in physiology, morphology and behaviour may enhance their invasion success. This plasticity may allow for rapid acclimation to novel ecological pressures they encounter within their new environment to quickly rise to ecological dominance.

Many invasive ants possess a suite of shared characteristics that facilitate their success within new/disturbed environments, such as a polygynous social structure (i.e., multiple reproductive queens), dependent colony foundation (i.e., budding) and lack of aggression among non-nestmate workers (Eyer & Vargo, 2021; Lester & Gruber, 2016; McGlynn, 1999; Tsutsui & Suarez, 2003). A polygynous social structure may enhance the survival rate of a colony, as the colony can withstand the death of a single queen or multiple queens. The reproduction of multiple queens also allows for greater colony growth because it relaxes the constraint on the upper limit of their egg-laying capacity (Boomsma et al., 2014; Boulay et al., 2014). Oftentimes, polygyny is associated with colony foundation through budding (Cronin et al., 2013). This dispersal strategy entails the founding of new colonies by queens assisted by workers, dispersing from their natal nests on foot to establish new nests nearby (Hölldobler & Wilson, 1977; Keller, 1991). Colony foundation through budding is associated with high foundation success, as the help of workers increase survival and reproduction of new nests during the early establishment stage (Cronin et al., 2013). However, this mode of foundation restricts dispersal of the species, often leading to the establishment of many genetically similar colonies across a landscape and thereby a pattern of isolation-by-distance (Schultner et al., 2016). Interestingly, this reduction in dispersal may promote polygyny and polydomy, and may ultimately lead to the formation of supercolonies – extensive colonies comprised of many nests exchanging workers, queens, brood and resources (Tsutsui & Suarez, 2003). This colony structure eliminates intraspecific competition, leading to dense networks of interconnected nests, genetically distinguishable from each other. The development of highly polygynous supercolonies enables invasive populations to reach tremendous densities and rapidly outcompete native species by allocating a high number of workers to monopolize resources (Tsutsui & Suarez, 2003). For example, populations of the yellow crazy ant Anoplolepis gracilipes and the little fire ant Wasmannia auropunctata can reach densities of up to 20 million and 240 million ants per hectare, respectively (Abbott, 2005; Souza et al., 2008). To date, the association of polygyny, dependent colony foundation and development of a dense polygynous nest structure have been observed in many invasive ants, such as Linepithema humile, Pheidole megacephala, Monomorium pharaonis and Nylanderia fulva (Buczkowski & Bennett, 2009; Eyer et al., 2018; Tsutsui et al., 2000).

Although invasions are generally associated with establishment in new countries or continents, they can also occur along a habitat continuum. The odorous house ant Tapinoma sessile is one such invader – native to a variety of natural habitats across North America (e.g., forests, grasslands, bogs, etc.), this ant has become highly abundant in urban environments throughout the United States (Buczkowski, 2010; Buczkowski & Bennett, 2008; Menke et al., 2010). Interestingly, like more traditional invasive ants, T. sessile exhibits a transition in its breeding system and social structure between its native and invasive populations. Colonies occurring in natural habitats are typically small (<200 workers) and consist of a single nest headed by a single queen (Buczkowski, 2010). On the other hand, urban colonies tend to be large (>100,000 workers) and made of several interconnected nests, each comprising numerous reproductive queens, with low internest aggression over large landscapes. This suggests the existence of supercolonies in this species within urban environments (Buczkowski, 2010; Buczkowski & Bennett, 2008; Menke et al., 2010). However, these assessments have only been based on behavioural studies (Buczkowski, 2010; Buczkowski & Bennett, 2008; Buczkowski & Krushelnycky, 2011), while the genetic underpinnings of the colonies have not been analysed. In T. sessile, four major mitochondrial clades have been described across the United States (Menke et al., 2010). Remarkably, this shift in life history traits has occurred consistently across its distribution, rather than all urban colonies originating from a single natural population (Menke et al., 2010). Therefore, plasticity in colony structure appears to be inherent within the species, and the repeated transition of small, monogynous natural habitat colonies to large, polygynous urban colonies resembles the invasions of more traditional invasive ants. Thus, T. sessile represents a unique opportunity to determine the factors driving these trait differences, which may provide insights into their evolutionary trajectory and broaden our understanding of the mechanisms linking them to species invasions.

Here, we conducted a large-scale analysis of the population and colony structure of T. sessile across the four geographic clades uncovered within the United States (Menke et al., 2010). For each of the four clades, we performed a paired sampling of one urban and one natural habitat in close geographic proximity (except for the Mountain clade in Colorado – see Methods). We first investigated the breeding structure of these populations to test for consistent transitions of monogynous colonies in natural habitats to polygynous colonies in urban areas, by assessing the number of queens per nest and the relatedness among nestmate workers. We then evaluated the colony structure of T. sessile in each locality by genetically inferring whether different nests belong to the same polydomous colony, testing for unicoloniality within urban habitats and multicoloniality within natural habitats. We also analysed whether workers
from different nests recognize each other as colony-mates through behavioural assays, testing for reduced aggression between non-nestmate workers in urban habitats compared to natural habitats, and assessed whether this discrimination toward non-nestmate workers is mediated through chemical cues. In addition, we investigated the dispersal ability of *T. sessile* by testing for an isolation-by-distance pattern in each locality and habitat. Finally, we discuss the potential evolutionary mechanisms enabling urban invasions by a native ant species, comparing these mechanisms with the life history traits shared by most invasive ant species.

2 | MATERIALS AND METHODS

2.1 | Study sites and sampling

Nests of *T. sessile* were collected from July of 2018 to August of 2020 in four localities across the United States: Bloomington, Indiana; Bay Area, California; Little Rock, Arkansas; and Boulder, Colorado (Figure 1a). These four localities correspond to the four geographic clades previously elucidated by Menke et al. (2010). For each locality, two sites in close geographic proximity were identified – one comprising the urban environment (residential or commercial areas) and the other comprising the natural environment, with fifteen nests collected in each habitat. No nests were found in the urban environment of Boulder, Colorado. Therefore, our total collection consisted of 104 nests across the four localities and seven total sites (details of the sampling are given in Table S1). Although *T. sessile* inhabits a variety of natural habitats, all natural collections were carried out within forests. As previous observations of the ant across several natural habitats are suggestive of a consistent natural disposition (Fellers, 1989; Kimball, 2016; Menke et al., 2010; Milford, 1999), we refer to our forest collections as natural colonies for the remainder of the paper.

In both habitats, entire nests were sampled to ensure a reliable count of queens and that ants collected belonged to the same nest, and no minimum collection distance was used between nests in order to not preclude the detection of polydomous colonies. The nests were transported to the laboratory and kept under standard conditions (28 ± 2°C, 12:12 h light period, and fed with an artificial ant diet (Dussutour & Simpson, 2008)). For each nest, eight workers were separately placed in 200 µl hexane for chemical analysis, while a subset of workers, queens and males were directly stored in 96% ethanol at 4°C for genetic analysis.

2.2 | Genetic analyses

The genomic DNA of eight workers and up to eight queens and males from each nest was extracted following a modified Gentra Puregene extraction method (Gentra Systems Inc.). Species-specific microsatellite primers do not exist for *T. sessile*; instead, we tested 39 markers shown to amplify in closely related species (Berman et al., 2014; Butler et al., 2014; Krieger & Keller, 1999; Zheng et al., 2018; Zima et al., 2016). Forward primers were affixed with an M13 tail to enable PCR multiplexing via fluorescent labelling with 6-FAM, VIC, PET, and NED (Boutin-Ganche et al., 2001). PCR conditions and multiplexing arrangements are given in the online Supporting Information (Table S2). PCR reactions were performed on a Bio-Rad thermocycler T100 (Bio-Rad). Multiplex PCR products were run on an ABI 3500 capillary sequencer (Applied Biosystems) along with the LIZ500 standard. Genotype v.9.1 was used for scoring alleles (Kearse et al., 2012). Of the 39 markers tested, 21 were discarded due to nonamplification or monomorphic amplification. The linkage disequilibrium (LD) for each pair of loci was tested for each locality separately using Genepop v.4.7 (Rousset, 2008), with p-values corrected via the Holm method to account for multiple comparisons (Holm, 1979). Loci exhibiting linkage disequilibrium were discarded from further analysis. Overall, the final data set includes 831 workers genotyped at 12 polymorphic microsatellite loci.

Sequencing of the cytochrome oxidase 1 (COI) mitochondrial gene was performed on at least one worker from each nest, with multiple workers from a nest sequenced if microsatellite genotypes suggested they originated from different queens (n = 145). Gene sequences were amplified using primers LepF1 and LepR1, targeting a 658-bp fragment (Hajibabaei et al., 2006; Hebert et al., 2004). PCR products were purified with EXOSAP-it PCR purification kit (Affymetrix) and sequenced using the ABI BigDye Terminator v.3.1 Cycle Sequencing Kit on an ABI 3500 Genetic Analyser (Applied Biosystems). Base calling and sequence reconciliation were performed using CodonCode Aligner (CodonCode Corporation).

2.3 | Population and colony structure analyses

2.3.1 | Mitochondrial data set

A Bayesian phylogenetic tree and a haplotype network were constructed to assign each nest into one of the four clades previously described by Menke et al. (2010). In addition, the mitochondrial dataset was used to test for the presence of multiple haplotypes within nests, which would indicate the reproduction of multiple unrelated queens. MrBayes v.3.2 was used to construct the tree (Ronquist et al., 2012), using the generalized time reversible model with gamma-distributed rate variation across sites and a proportion of invariant sites as the evolutionary model. Two simultaneous MCMC simulations ran for 2 x 10⁶ generations using four chains (three heated and one cold), with each run sampled every 500 generations. The mitochondrial network was produced via the median-joining method (Röhl et al., 1999) implemented in POPART (Leigh & Bryant, 2015). The COI gene was extracted from the complete mitochondrial genome sequence of *T. melanocophthalmum* to use as an outgroup for both analyses (Du et al., 2019). Additionally, sequence divergence was compared within and between habitats and populations of *T. sessile* using the Kimura 2-parameter model (Kimura, 1980) in MEGA v. 10.2.2 (Kumar et al., 2018; Tamura et al., 2011).
FIGURE 1  (a) Sampling locations of *Tapinoma sessile* across the United States. For each locality, nests were sampled in both natural and urban environments, depicted as light-coloured (natural) and dark-coloured (urban) numbers in the figure. The thickened black lines connecting some nests represent nests that were found to belong to the same colony. Additionally, the stars next to each number denote the social structure of the colony - white and black stars represent monogyne and polygyne colonies, respectively. Note that for each locality, the counting always begins with the first natural nest; also, note that no urban nests were found in Colorado. (b) Bayesian inference tree based on 145 COI sequences of *T. sessile* across the four localities, with one *T. melanocephalum* sequence as an outgroup. (c) PCA based on the microsatellite data of each individual from each nest sampled in the overall data set (dots represent individuals). (d) STRUCTURE analysis based on the microsatellite data across four values of $K$, which correspond to the levels of hierarchy present within the overall data set (2 = habitat; 4 = locality; 7 = habitat x locality)
2.3.2 | Microsatellite data set

The number and frequency of alleles, F-statistics (Weir & Cockerham, 1984), and observed and expected heterozygosity (Nei, 1987) were calculated for each microsatellite marker, and for each locality and habitat (as well as overall values) using FSTAT v2.9.4 (Goudet, 2003). For the overall dataset, the hierarchical partitioning of the genetic diversity between localities, between habitats within localities, between nests within habitats, between individuals within nests, and within individuals was assessed using an analysis of molecular variance (AMOVA) implemented in the ade4 R package (Dray & Dufour, 2007; R Core Team, 2020) via Poppr (Kamvar et al., 2014).

Three complementary approaches were used to determine whether workers collected from different nests belonged to the same colony. First, genotypic differentiation between each pair of nests within localities was tested using the log-likelihood G test implemented in GENEPOP v.4.7 (Rousset, 2008). Nests were considered distinct colonies if genotypic differentiation was found to be significantly different using Fisher’s test together with the Holm method to account for multiple comparisons (Holm, 1979). Second, population structure was visualized with a principal component analysis (PCA) using the dudi.pca function in the adegenet R package (Jombart, 2008; R Core Team, 2020). Third, the presence of genetic structure was tested using the Bayesian clustering method implemented in STRUCTURE v.2.3.4 (Falush et al., 2003; Pritchard et al., 2000). Simulations were run for K (i.e., genetic clusters) ranging from 1 to the maximum number of nests per data set, with each run of K replicated 20 times. The analyses were run under the admixture model with correlated allele frequencies enabled. Each run was initiated with a 50,000 burnin period, followed by 100,000 iterations of the MCMC. The most likely number of genetic clusters (K) was inferred using the methods of both Evanno et al. (2005) and Puechmaille (2016), with the output visualized via CLUMPKIT (Kopelman et al., 2015), as implemented in the web-based software StructureSelector (Li & Liu, 2018). The method of Puechmaille (2016) aims at unraveling finer partitioning in the data, whereas the Evanno et al. (2005) method aims at describing the primary partitioning. Finally, isolation-by-distance analyses were performed with Mantel tests using the vegan R package (Oksanen et al., 2020; R Core Team, 2020), between matrices of genetic differentiation ($F_{ST}$) and geographic distance. The PCA, STRUCTURE and isolation-by-distance analyses were first performed for the overall data set, then for each locality, and finally for each habitat within each locality.

2.4 | Breeding structure analyses

We estimated the number of queens per nest and the genetic relatedness among nestmate workers for each locality and habitat. We also explored the possibility that queens use thelytokous parthenogenesis for the production of new queens, as this strategy was previously reported in several invasive ant species (Fournier et al., 2005; Pearcy, Goodismann et al., 2011; Rabeling & Kronauer, 2013). The presence (or lack thereof) of multiple queens per nest was first determined directly from field observations. For each nest, polygyny was confirmed genetically through the presence of multiple mitochondrial haplotypes and through the composition of worker microsatellite genotypes. Polygyny was inferred when worker genotypes could not be reliably assigned to a single queen (all workers carrying one of the two alleles of the mother queen at all microsatellite markers).

Relatedness coefficients (r) among nests were estimated using COANCESTRY v.1.0.1.9 (Wang, 2011), following algorithms described by Queller and Goodnight (1989). As differences in allele frequencies may exist between localities, relatedness coefficients were calculated separately for each of the localities. Additionally, relatedness coefficients were estimated at three separate levels – (1) between workers, (2) between queens, and (3) between workers and queens. Finally, we evaluated whether queens produce new queens through thelytokous parthenogenesis by comparing the heterozygosity level and relatedness between castes in each locality. As automictic thelytokous parthenogenesis generally increases homozygosity over time (Pearcy et al., 2006; Pearcy, Hardy, et al., 2011; but see Rey et al., 2011), a decrease in observed heterozygosity and increase in relatedness should be present in the parthenogenetically produced queens when compared against sexually produced workers. For these and all further comparative analyses, figures were generated using the ggsstatsplot R package (Patil, 2021).

2.4.1 | Chemical analyses

Chemical differentiation between nests was determined by analysing eight randomly chosen workers per nest using GC–MS. Individual ants were knock-downed for 1 min at −20°C and extracted in 200 μl hexane for 5 min with intermittent gentle mixing. Extracts were evaporated under a stream of high-purity nitrogen, redissolved in 35 μl of hexane and transferred to a 100 μl insert in a 1.5 ml autoinjection vial. A volume of 2 μl was injected in splitless mode using a 7693B Agilent autosampler into a HP-5MS UI column (30 m × 0.250 mm internal diameter × 0.25 μm film thickness; Agilent) with ultrahigh-purity helium as carrier gas (0.75 ml/min constant flow rate). The column was held at 50°C for 1 min, increased to 320°C at 10°C/min, and held at 320°C for the last 10 min. The overall chemical profile of each individual was investigated by calculating the relative abundance of each compound. All compounds occurring in at least 10 samples were used to calculate the chemical profile of individuals, but we did not aim at identifying the different chemical compounds. The chemical profile of individuals was compared between nests, localities and populations.

We performed a PCA using ade4 (Dray & Dufour, 2007; R Core Team, 2020) in order to visualize the variation within and between nests. Additionally, we estimated the pairwise cuticular hydrocarbon (CHC) differentiation between each nest through the calculation of the Euclidean distance between nest centroids. We then assessed the level of CHC variation within each nest by calculating the average Euclidean distance between each of the eight workers and the centroid of the nest. The between nest and within nest calculations...
were performed on the first two PC’s from the PCA. We first tested whether the level of CHC variation within nests differs between native and urban environments, as well as between monogyne and polygyne nests. Finally, we tested whether this level of CHC variation within a nest increases with genetic diversity (using expected heterozygosity as a proxy), and whether the level of CHC differentiation between nests increases with genetic differentiation or geographic distance, with significance determined using Student’s t-distribution for Pearson’s correlation coefficient.

2.4.2 | Behavioural assays

Aggression assays were performed by randomly selecting a single worker from two distinct nests and placing them together in a 5 cm diameter petri dish for 5 min. The sides of the petri dish were coated with Fluon to prevent the ants from escaping, and the bottom of the petri dish was covered with filter paper that was changed between trials to prevent odor transfer between trials. The subsequent behavioural interactions were scored on a four-level scale of escalating aggression (Suarez et al., 1999): (1) touch (contacts that included prolonged antennation), (2) avoid (contacts that resulted in one or both ants quickly retreating in opposite directions), (3) aggression (lunging, biting, and pulling legs or antennae), or (4) fight (prolonged aggression between individuals). For each trial, the highest level of aggression was recorded, with the mean of 10 trials for each nest pairing used to calculate an average aggression score between nests. Pairs of nests assigned to the same colony based on microsatellite markers were used as a control for this experiment. Twenty-five nest combinations were tested in Arkansas, California and Indiana (10 urban-urban, 10 natural-natural and 5 urban-natural) and 10 were tested in Colorado (10 natural-natural; no urban colonies found) for a total of 850 trials (85 nest combinations x 10 trials). Nests were matched across a short (minimum 0.001 km) to long-distance (maximum 26 km) gradient to identify whether geographic distance influenced aggression between nests. Similarly, aggression was compared against both genetic and chemical differentiation. The significance of all three relationships was evaluated using Student’s t distribution for Pearson’s correlation coefficient. Finally, aggression levels among and between urban and natural nests were compared using Kruskal-Wallis tests, with Dunn’s test utilized to elucidate significant pairwise relationships and p-values adjusted by the Holm method to account for multiple comparisons.

3 | RESULTS

3.1 | Population and colony structure analyses

3.1.1 | Mitochondrial data set

A total of 68 mitochondrial haplotypes were identified, of which 36 were shared between individuals. The mean genetic distance between localities was 0.079, while it was only 0.039 within localities (Table S3). Mitochondrial haplotypes were rarely shared between localities (i.e., a single one shared between Arkansas and Indiana). Yet, the topology of the tree did not align completely with geography and therefore did not concur entirely with the four geographic clades previously uncovered by Menke et al. (2010) (Figure 1b; the mitochondrial network is provided in Figure S1). Notably, a substantial portion of the eastern US samples (i.e., Indiana and Arkansas) intermix with one another and appear on three distinct branches of the tree. Additionally, two samples from California were located nearest to the two basal eastern US branches, while samples from Colorado were split across two clades.

Our results further confirmed the finding of Menke et al. (2010) that mitochondrial haplotypes were commonly shared between monogyne and polygyne social structures (n = 12 – dispersed across all localities). However, haplotypes were rarely shared between natural and urban habitats, as only a single haplotype was shared between the two (in Indiana; Figure 1b and Figure S1), suggesting that little genetic exchange occurs between habitats. Finally, the presence of multiple haplotypes within a nest was rare (n = 7 nests – only in the eastern US), suggesting polygyne colonies primarily develop via the association of related queens.

3.1.2 | Microsatellite data set

The 12 microsatellite markers used in this study contained an average of 12.6 alleles (range = 3–49; Table S4). When split by habitat, the natural and urban datasets contained an average of 9.8 (range = 3–38) and 9.2 (range = 3–37) alleles, respectively (Table S4). Therefore, the allelic diversity was not significantly different between natural and urban habitats (Mann-Whitney U = 4.31, p = .907). Furthermore, the allelic diversity was not significantly different between any of the four localities (Kruskal-Wallis H = 1.72, p = .633).

In the overall data set, the AMOVA analysis revealed slight genetic diversity partitioned between localities (10.6%), with more substantial levels partitioned between habitats within localities (23.9%), between nests within habitats (27.2%), and within individuals themselves (45.5%; Table S5). The difference between localities is mostly driven by a clear separation of the eastern US samples (i.e., Indiana and Arkansas) from the western localities (i.e., Colorado and California) observed at K = 2 (Figure 1c,d). Consistently, Mantel tests identified significant isolation-by-distance when analysing localities as a whole (Figure S2), contrasting the results obtained by the mitochondrial marker, where eastern and western populations did not segregate into two clearly distinct clades. Interestingly, at K = 4, the eastern US samples grouped by habitat rather than by locality, despite being geographically distant (Figure 1d). To a lesser extent, a similar pattern can be seen in the western localities, as the natural habitats of California and Colorado mostly grouped together (Figure 1d). At K = 7, both the localities and the habitats within localities clustered independently (Figure 1d), highlighting that the overall distribution of genetic variability is strongly influenced by both geographic distance and habitat.
Within localities, strong differentiation (i.e., high $F_{ST}$) was found between almost every nest (Table 1, Figure S3). Similarly, $G$ tests revealed that most nests represented a single genetic entity. Of the nest pairs that could not be differentiated, 11 were in the urban environment and two were in the natural environment (Supporting Information Data Appendix S1). STRUCTURE analyses using the method of Puechmaille (2016) (i.e., finer partitioning) produced corroborating results, with best $K$ mostly segregating each nest as its own genetic cluster (Figure 2). However, two trios of geographically adjacent nests were not genetically different from each other in urban habitats within California (nests 22–24) and Arkansas (nests 23–24, 29; Figures 1a and 2b,c). These two trios of nests also clustered together when urban habitats were analysed separately from the natural habitat (Figure S4).

Remarkably, the Evanno et al. (2005) method (i.e., primary partitioning) consistently depicted clear separation between urban and natural habitats (Figure 2). $K = 2$ best explained the structure in the data for each locality and mostly segregated urban and natural colonies into two distinct clusters (Figure 2). This strong dichotomy between urban and natural habitats was also highlighted using PCAs within each locality (Figure 2). No isolation-by-distance was found when analysing each habitat separately within localities (all $p > .05$; Figure S4); however, isolation-by-distance was significant when comparisons between habitats within localities were considered ($p = .001, .001$ and $.016$ for Indiana, Arkansas and California respectively; Figure 3a). Indeed, the interhabitat genetic differentiation between nests was always higher than the differentiation between nests within a habitat (Figure 3b). However, the genetic differentiation between nests mostly did not differ across the two habitats (Figure 3b). AMOVAs for each locality were similar to the overall data set, with most genetic diversity partitioned within individuals (avg. = 50%), and substantial amounts partitioned between habitats (avg. = 26%) and nests within each habitat (avg. = 31%; Table S6). Taken together, these results suggest that most nests sampled across the four localities represent distinct colonies. They also highlight the substantial differentiation between urban and natural populations and support the continent-wide observation that colonies of $T$. sessile grouped by habitat rather than by locality within the eastern and western populations.

3.2 Breeding structure analyses

Overall, the urban environment contained significantly more polygyne nests (67%) than the natural environment (38%, $p = .002$; Figure 4a). Although both social structures were found in both habitats, the number of queens collected per nest was significantly higher in urban habitats (mean ± SD = 13.00 ± 15.70, up to 62) than natural habitats (mean ± SD = 2.61 ± 3.76, up to 21; Figure 4a). This pattern was found for the overall data set ($p < .001$), as well as for each locality separately (despite being non-significant for Indiana, $p = .117$).

Accordingly, the coefficient of relatedness between workers was significantly higher in the natural environment ($R_{w-w} = 0.74$) than in the urban environment ($R_{w-w} = 0.65$). This association was found significant for the overall dataset ($p < .001$), as well as for each locality separately (all $p < .05$; Figure 4b). However, the relatedness among workers was surprisingly high considering the number of queens present in each nest. This is especially true for urban nests (mean $R_{w-w} = 0.61, 0.72$ and 0.61 for the urban habitats of Arkansas, California and Indiana, respectively), as they usually contained a high number of queens. No values of relatedness were found close to zero (lowest value was 0.22), which is expected under a random association of a high number of queens or with the free movement of individuals among nests across the population.

Although natural nests were significantly more outbred (i.e., lower negative $F_{IS}$) than their urban counterparts ($p < .001$; Table 1), the high relatedness within urban nests does not appear to stem from inbreeding (mean $F_{IS} = -0.015$). This suggests that queens do not exclusively participate in intranidal mating, although some level is likely considering the high relatedness values (and has been thought to occur in $T$. sessile – see Kannowski (1959)). Finally, the relatedness among queens within nests was also high ($R_{Q-Q} = 0.68$ and
0.66, for natural and urban polygynes nests, respectively), an uncommon finding for a polygynous ant and indicative of daughter queens being retained within their natal nest. However, this relatedness was not significantly higher (Figure S5) and the observed heterozygosity not significantly lower (Figure S6) when compared to the worker caste in any of the localities, suggesting that new queens are not produced asexually.

3.2.1 Chemical analyses

Population clustering based on the CHCs yielded similar results to those of the genetic analyses. At the overall scale, substantial chemical differentiation was found between localities, with the eastern US, California, and Colorado samples appearing distinct from one another (Figures S3 and S7). Consequently, CHC differentiation was
significantly positively correlated with both geographic distance and genetic differentiation at the overall level (Figure S7). The Colorado samples were completely separate from the California samples, despite appearing genetically similar to samples from the California natural habitat. Interestingly, the urban and natural habitats from Arkansas, as well as the urban habitat from Indiana, clustered together chemically (Figures S3 and S7).

The chemical segregation of nests between natural and urban habitats became clearer when clustering analyses were performed at the locality level (Figure 5). Like the genetic differentiation, the chemical differentiation was mostly higher between nests from distinct habitats than between nests from the same habitat within a given locality (Figure 5). Consequently, the chemical differentiation between nests is associated within both genetic differentiation and geographic distance within most localities (Figure S8). Interestingly, nests 3 and 4 from the natural habitat of Indiana clustered with the urban habitat both genetically (Figure 2a) and chemically (Figure 5a). Overall, these findings suggest that chemical differentiation is influenced by both genetic and environmental factors, and therefore by the clear effect of habitat on the genetic differentiation mentioned above.

Interestingly, the within-nest CHC variation was not significantly different between monogyne and polygyne nests in any locality or for the overall dataset. However, the within-nest variation was significantly different between natural and urban nests, with natural nests having increased variation at the overall level; a similar, but not significant, pattern was also observed within each locality (Figure S9). No significant correlations between CHC variation and genetic diversity were found within any locality (Figure S8).

3.2.2 | Behavioural assays

Aggression assays further demonstrated that most nests appear to be distinct colonies. The overwhelming majority of pairings obtained aggression scores of 3 or 4, with significant differences between groups mainly driven by slight fluctuations in avoidance/aggressive behaviours (Figure 6). The notable exception to these aggressive behaviours occurred in the California urban plot, where a more even distribution of aggression scores resulted from the lack of aggression between the trio of nests collected in San
FIGURE 4  Breeding structure of Tapinoma sessile overall and across the four localities. (a) The percentage of monogyne and polygyne nests in natural and urban habitats, as well as the number of queens collected in nests where at least one queen was found. (b) The average relatedness among workers within a nest in urban and natural habitats. For both (a) and (b), each smaller dot represents a nest, and each gold dot denotes the mean of the habitat.
Francisco, California (nests 22–24; Figures 1a and 6). A similar trio of nests without aggression were also collected from the urban environment in Little Rock, Arkansas (nests 23–24, 29; see Figure 1a). Given that the genetic analyses above also support that the trio of nests in both cities comprise a single genetic entity, these two sites potentially represent supercolonies, albeit geographically limited (approximately 7500 and 3600 m² in California and Arkansas, respectively).

The correlation analyses revealed little link between aggression and geographic distance, genetic differentiation or chemical differentiation (Figure S10), most probably driven by the high aggression that was observed in most aggression assays. Again, the notable exceptions here were the urban San Francisco and Little Rock sites mentioned above, as low genetic differentiation and aggression between some nests at these sites led to a significant positive correlation between genetic differentiation and aggression (Figure S10).

4 | DISCUSSION

Our extensive phylogenetic, chemical and behavioural study revealed several insights into the colony and breeding structure of T. sessile across the United States. First, we confirmed that the social structure of a colony appears to be a plastic trait found in both natural and urban habitats; however, we did find monogyny prevalent in the natural habitat and polygyny more common in urban habitats. Furthermore, the extent of polygyny within nests was far greater in the urban habitat; however, differentiation was present between almost every nest in each locality and habitat. This finding, supported by our chemical and behavioural analyses, suggests that urban colonies mostly do not consist of large supercolonies. Yet, two trios of nests in two separate urban habitats lacked genetic, chemical and behavioural differentiation. As no such polydomous colonies were found in any natural habitat, this suggests only the urban environment harbors the necessary conditions for supercolony formation.
Interestingly, our results uncovered clear genetic and chemical differentiation between natural and urban populations. This clear separation was observed within each locality, and also at a large geographic scale as nests clustered by habitat rather than by locality within the eastern and western clades. These findings suggest that urbanization acts as a strong barrier to gene flow in this species, with the heterogeneity of suitable habitat within cities potentially limiting immigration and emigration. Additionally, the clustering of nests by habitat rather than by locality may denote a strong signature of selection for the urban environment, with specific genotypes most probably found within cities. Overall, these results provide further support for urbanization as an intense driver of evolution.

Modified ecological interactions within the urban environment are known to affect the composition of communities and have been specifically shown to promote the abundance of arthropods (Faeth et al., 2011), including ants (Vonshak & Gordon, 2015). Therefore, certain characteristics of urban habitats may have allowed for T. sessile to achieve larger colony sizes than their natural conspecifics. For one, the abundance of traditionally limited resources may have stabilized, or even increased, colony productivity within urban habitats (Faeth et al., 2005; Shochat et al., 2006). For example, such a release and subsequent increase in productivity within urban environments has been shown to lead to larger body sizes in both mammals (Hantak et al., 2021) and guppies (Santana Marques et al., 2020). Additionally, increases in temperature in the winter (Arnfield, 2003; Oke, 1982) may extend the foraging and worker production season for urban colonies (Shochat et al., 2006, 2010). Furthermore, fluctuations between seasons are lessened and extreme climate events buffered, which have been documented to prolong urban breeding seasons (Lowry et al., 2013; Shochat et al., 2006). Therefore, these highly productive environments may be providing favourable breeding conditions throughout most of the year, possibly contributing to the large colony sizes T. sessile attains in cities.

However, although urbanization may reduce resource variation through time, resource variation in space may be intensified compared to natural habitats. Urban landscapes are often associated with a patchy distribution of resources (Cadenasso et al., 2007), which might have profound consequences on the evolution of dispersal traits in urban populations. Generally, costs of dispersal (e.g., loss of propagules, energetic demands) represent strong selective forces against dispersal (Bonte et al., 2012; Bowler & Benton, 2005). This is exemplified by the reduction in dispersal capability of island bird populations because a lack of predators nullifies the benefit flight offers as a predator-avoidance technique (Carlquist, 1966a; McNab, 1994; Wright et al., 2016), as well as in island plant and insect populations due to the high risk of landing in the ocean (Carlquist, 1966a, 1966b; Cody & Overton, 1996; Roff, 1990). Similarly, the fragmented nature of urban environments may increase the failure rate of dispersers, and therefore select against dispersal. For example, urban populations of the pavement weed Crepis sancta produce a higher proportion of nondispersing plants compared to their unfragmented natural populations (Cheptou et al., 2008). Finally, frequent disturbances within urban environments may increase the success of dependent colony foundation (i.e., shorter dispersal) rather than decrease the success of independent foundation (i.e., longer dispersal). In ants, Tsuji and Tsuji (1996) demonstrated that dependent colony foundation should be favoured in environments where the intrinsic rate of natural increase (r) is high because the generation time of a queen is shortened. Urban areas are frequently disturbed habitats,
which probably represent such high r-inducing environments (Tsuij, 2006). Further ecological models based on spatial structure found that dependent foundation was favoured over long-distance independent foundation in frequently disturbed habitats of relatively small spatial scale, despite its inherent costs (e.g., short dispersal distance, reduced production of differentiated colonies (Schultner et al., 2016)) (Nakamaru et al., 2007, 2014). In short, frequent, local-scale ecological disturbances can create free space near the natal nest, which can then be more rapidly occupied by queens dispersing on foot through budding than by queens dispersing on wing. Overall, reduced nest-site availability due to habitat patchiness and/or frequent disturbance within urban environments may be selecting for reduced dispersal of new queens and favoring the establishment of new colonies via budding.

Notably, our results revealed surprisingly high levels of relatedness within urban colonies, including highly polygynous ones. These high relatedness values (~0.6) not only suggest that queens are retained during colony growth, but also that some form of colony inheritance by one maternal lineage takes place every generation. The retention and subsequent inheritance of daughter queens from the same lineage would prevent the drastic loss of relatedness that the integration of new unrelated queens would otherwise cause, as well as prevent colony boundary collapse through a subsequent loss of non-nestmate discrimination. Interestingly, the development of large polydomous colonies observed in two urban localities was also not associated with a loss of relatedness among nestmate workers when compared to the genetic background of the locality. This finding supports the hypothesis that large polygynous/polydomous colonies arise through the extreme growth of a single colony (Helanterä et al., 2009), probably through a combination of retaining daughter queens and the dependent colony foundation mentioned above. This hypothesis of supercolony development in invasive species supposes that polygyny and polydomy are pre-existing traits of the species within its native range (e.g., Fournier et al., 2012; Pedersen et al., 2006); indeed, we found myrmicine are pre-existing traits of the species within its native range development in invasive species supposes that polygyny and polydomy are pre-existing traits of the species within its native range. This hypothesis of supercolony development combined with male-biased dispersal within urban populations may explain the elevated levels of inbreeding compared to natural populations, as well the strong genetic sub-structure between most nests. However, another possible explanation may be that structure does exist within the urban environment and was simply not detected because we did not perform a focused transect study. If this is the case, perhaps enhanced female philopatry and dependent colony foundation alone could explain the elevated levels of inbreeding within urban environments.

Isolation-by-distance was found to be significant when analysing both habitats together within a locality, highlighting the stark differentiation present between natural and urban populations. The minimal amount of gene flow between the two habitats suggests some selective force acting against interhabitat colonization, as well as implies selection for certain traits within each environment. A genetic signature of rapid anthropogenic evolution has been purported for many species (Hendry et al., 2008), although a more recent review found a lack of conclusive evidence for many studies (Lambert et al., 2020). Rates of phenotypic change have been shown to be elevated in urban systems (Alberti et al., 2017), which are potentially driven by changes in the underlying genotypes. Variation in ecological conditions can certainly drive evolutionary shifts in species’ life history traits, but whether phenotypic shifts are primarily the result of genetic adaptations to urban environments via selection or simply phenotypic plasticity is unclear (Palkovacs & Hendry, 2010). Such a phenotypic shift has occurred in urban populations of the acorn ant Temnothorax curvispinosus, with urban workers exhibiting higher heat tolerance and diminished cold tolerance compared to natural populations (Diamond et al., 2018; Perez et al., 2018). A similar divergence was found between field-born workers and workers raised for two generations in the lab, indicating that such differences between habitats is driven by evolutionary divergence through selection.
rather than simply plasticity (Martin et al., 2019). Reciprocal transplant experiments corroborated these results, with *T. curvispinosus* colonies experiencing higher survival in natal habitats compared to novel habitats, and local colonies displaying higher survival rates than foreign colonies (Martin et al., 2021).

Interestingly, the two localities in the eastern United States grouped genetically by habitat rather than by locality. While this result makes sense for natural populations given the few barriers to gene flow between these regions of the country, it runs counter to several recent studies in other species which found heightened differentiation among distinct urban populations (Björklund et al., 2010; Jason et al., 2016; Lourenço et al., 2017). However, gene flow between isolated urban populations may be sustained through human-mediated dispersal (Crispo et al., 2011). Such a scenario has been coined the "urban facilitation model", whereby human-facilitated gene flow reduces differentiation between urban populations and may actually increase urban genetic diversity through the introduction of novel alleles (Miles et al., 2018, 2019). Indeed, invasion rates of ants have been shown to strongly correlate with waves of human globalization (Bertelsmeier et al., 2017), and a recent study on the tiny acorn ant *Temnothorax nylanderi* identified no significant differentiation between populations in distinct cities across France (Khimoun et al., 2020), highlighting that ants may be prime candidates for human-mediated dispersal. Considering selective pressures probably differ between the urban and nonurban habitats, connections between urban sites may facilitate the evolution of an "urban ecotype" (Schapira & Boutsika, 2012; Yakub & Tiffin, 2017). A more in-depth sampling scheme across the eastern United States is needed to test for such a gene flow assisted convergence in *Tapinoma sessile*.

5 | Conclusion

Convergent selection between distinct urban populations has been found across wide variety of taxa (Johnson et al., 2018; Reid et al., 2016; Theodorou et al., 2021; Yakub & Tiffin, 2017), suggesting attributes of the anthropogenic environment impart a homogenous influence upon evolution. Our study not only demonstrated the repeated life history shifts between natural and urban populations of *T. sessile*, but also highlighted the presence of significant genetic differentiation between these populations. However, as mentioned previously, all natural collections for this study took place within forests, which may not fully represent the natural phenotype. Future sampling throughout the many natural habitats occupied by *T. sessile* may elucidate potential habitat-associated variation. Additional studies are also needed to further characterize the influence of urbanization on this ant. For example, transect sampling may be performed to test for the presence of isolation-by-distance within urban environments and to evaluate whether the reduction of gene flow along the natural-to-urban habitat gradient is progressive or abrupt. Also, a genomic approach could help identify consistent genomic regions under selection to the urban environment across different US cities. Overall, these results reinforce the need for multifaceted approaches in identifying signatures of local adaptation (Rivkin et al., 2019) and thereby the potential drivers of selection within cities (Lambert et al., 2020), as well as underscore the urban landscape as a powerful evolutionary force.
